Lower Cenomanian

Western France

ABSTRACT

Two fossil localities are reported on the "LGV SEA" railroad from the Lower Cenomanian of Jaunay-Clan (JC), near Poitiers, western France. The laminated mudstones yielded plant fossils including ferns (*Cladophlebis*, *Osmundophyllum*, *Ruffordia goeppertii*, *Sphenopteris*), conifers (*Brachiphyllum*, *Dammarophyllum*, *Pagiophyllum*), and terrestrial and aquatic freshwater angiosperms (*Eucalyptolaurus depreii*, *Ploufolia*). They are associated with a coleopteran insect that shows systematic affinities to the modern subfamily Chrysomelinae (Chrysomelidae). This assemblage suggests connections with arborescent vegetation growing in calm freshwater environment. Brackish to marine invertebrates also occur and include a dakoticancroid crab (*Brachyura*, *Podotremata*, *Dakoticancroidea*) and a few bivalves (*Brachidontes*). They suggest brackish episodes during pond sedimentation in a coastal environment. Lastly, vertebrates are represented by an isolated feather.

RÉSUMÉ

Deux nouvelles localités fossilifères sont découvertes sur la voie de chemin de fer de la « LGV SEA », dans le Cénomanien inférieur de Jaunay-Clan (JC), près de Poitiers, dans l'Ouest de la France. Des dépôts argileux finement laminés ont livré un grand nombre de plantes fossiles, comprenant des fougères (*Cladophlebis*, *Osmundophyllum*, *Ruffordia goeppertii*, *Sphenopteris*), des conifères (*Brachiphyllum*, *Dammarophyllum*, *Pagiophyllum*), ainsi que des angiospermes terrestres et aquatiques (*Eucalyptolaurus depreii*, *Ploufolia*). Ils sont associés

à un insecte coléoptère présentant des affinités systématiques avec la sous-famille moderne des Chrysomelinae (Chrysomelidae). Cet assemblage suggère des connexions avec une végétation arborescente poussant dans un environnement dulçaquicole calme. Des invertébrés saumâtres à marins ont été trouvés également et incluent un crabe de type dakoticancroïde (Brachyura, Podotremata, Dakoticancroidea) et quelques bivalves (*Brachidontes*). Ils suggèrent des épisodes saumâtres durant la sédimentation dans un milieu paralique en position côtière/lagunaire. Enfin, les vertébrés sont représentés par une plume isolée.

1. Introduction

In the last decade, several fossil plant localities have been reported from the Cretaceous of western France (Gomez et al., 2004, 2008; Néraudeau et al., 2002, 2003, 2005, 2008, 2009, 2012, 2013). By contrast, the department of Vienne (86) is well-known in the southwestern part of the Paris basin for marine fossil assemblages, especially from the Upper Jurassic deposits and the Cenomanian “Green Sandstones” (Mathieu, 1968). Albian–Cenomanian continental, estuarine and paralic sediments have limited exposures (Joubert, 1980).

During the years 2012 and 2013, the digging works for the railroad “LGV SEA” between Tours and Bordeaux have exposed numerous Cenomanian continental, and particularly estuarine and paralic deposits. Repeated field prospections have been led by XV and PF following a license of research established by private developers. Two new localities, Ormeau-Saint-Denis (JCO) and Bergère (JCB), were collected for fossil remains nearby the village of Jaunay-Clan 15 km from Poitiers (Fig. 1). They yielded well-preserved, abundant plant assemblages associated with crustaceans and insects. We report and describe for the first time these Cenomanian animal and plant assemblages.

2. Geological context

The Lower Cenomanian succession has been thoroughly described in the studied area (Alvarez, 1980; Joubert, 1980; Le Touzé de Longuemar, 1870). Briefly, Lower Cenomanian deposits overlay a paleokarst surface developed over a Callovian–Oxfordian limestone platform (Mathieu, 1960). Lowermost beds consist of finely laminated lignitic mudstones that progressively grade to 1 to 10-m-thick laminated, unfossiliferous grey silts. They are usually overlaid by 10 to 30-m-thick glauconious sands with rare decimeter-thick carbonate beds (also called the Furigny sandstones; Alvarez, 1980). The 10 uppermost meters of the Lower Cenomanian succession are glauconious sandstones commonly intercalated with decimeter-thick beds of laminated grey marls (Joubert, 1980).

At the Ormeau-Saint-Denis locality (JCO), the paleokarst surface is covered by a decimeter-thick bed of bivalve-bearing mudstones (Fig. 2); the uppermost layers of these mudstones bear abundant fossil plant remains. This bed is overlaid by a lag of coarse clasts, including mudclasts and reworked pisolithes that precede the Lower Cenomanian succession, first decimeters of which are also rich in fossil remains (Figs. 1 and 2). At the Bergère locality (JCB), the

paleokarst surface displays a partly preserved paleosol profile resembling those observed on the Jurassic rings of the Paris Basin (Thiry et al., 2006), consisting of 20 to 60-cm-thick ochre clay overlaid by a 20-cm-thick ferruginous crust made of iron pisolithes. The profile is overlaid by a 1-m-thick and 10-m-wide pocket of green-gray mudstones that fills a small depression of the paleokarst surface (Fig. 1). These mudstones display poorly preserved laminations rich in plant debris and vertical millimeter-thick root traces. They are overlaid by a lag of coarse clasts that precedes the Lower Cenomanian succession and are stratigraphically correlated with the conglomeratic lag observed at Ormeau-Saint-Denis locality. Accordingly, the lowermost mudstone beds of both sites are interpreted as deposited in a probably alternating freshwater and brackish, pond-like environments at the beginning of the Cenomanian transgression.

3. Material and methods

We prospected exposures along the “LGV SEA” railroad during the weekends following an agreement with the companies LISEA and COSEA (VINCI group) (Fig. 2a). In particular, we ran two large excavations of 120 square meters each, digging 2.5 meters in depth with 20 volunteers, at Ormeau-Saint-Denis (JCO) and Bergère (JCB) between May and October 2013 (Fig. 2b and c).

We split apart clayey slabs with knives to locate fossils and millimetric amber pieces. In JCB, plant fossils were so dense and interbedded that we had to collect large blocks of mudstone and wrapped them with plaster jackets. Wet rock specimens were wrapped in cellophane to limit fast dehydration and broken fossils. More than 400 mudstone specimens with plant fossils have been collected. They are housed in the collections of the University of Poitiers (UP) under the numbers UP-JCO year-number and UP-JCB year-number. Photographs were taken with a Canon EOS 60D coupled to a Canon macrolens EF 100 mm. The beetle and crab specimens were studied using a stereomicroscope Olympus SCX9.

4. Paleobotany and paleontology

4.1. Plants

Ferns are the less abundant plant remains. Fragments of three sterile pinnae consist of a narrow rachis bearing pinnules alternately on both sides (Fig. 3a–e). Pinnules are triangular to lanceolate. The pinnules are attached by a

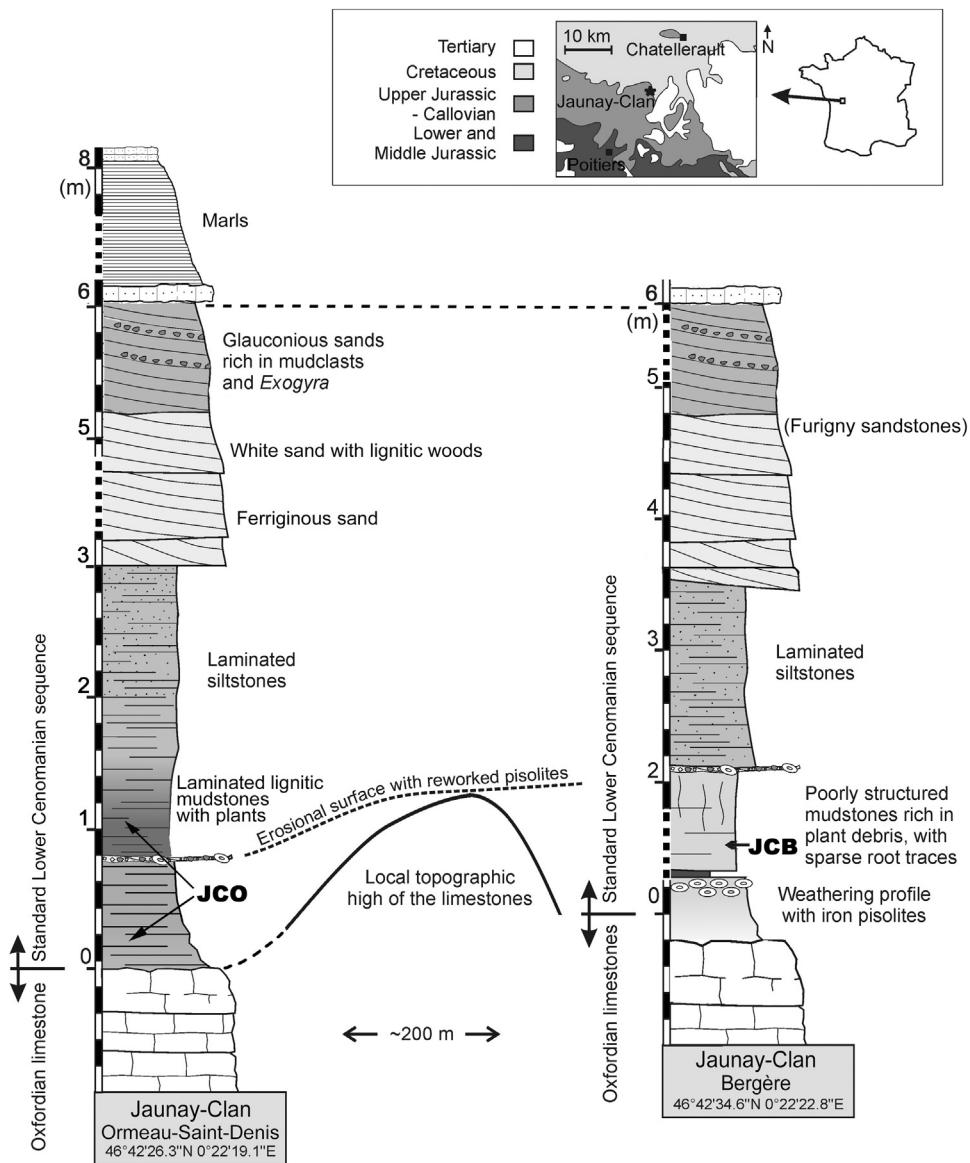

Fig. 1. Synthetic logs of Ormeau-Saint-Denis (JCO) and Bergère (JCB) near the village of Jaunay-Clan, showing the first meters of Lower Cenomanian overlying the Oxfordian limestones.

Fig. 1. Logs synthétiques des deux localités Ormeau-Saint-Denis (JCO) et Bergère (JCB), situées près du village de Jaunay-Clan, montrant les premiers mètres du Cénomanien inférieur qui surmontent les calcaires oxfordiens.

broad base, with an acroscopic sinus and basiscopic decurrent margin. The margin is typically entire or lobed basally at the proximal and distal part of pinnae (Fig. 3a–c). Pinnules are slightly toothed half distally (Fig. 3a, b, d, and e). One- to three-time-dichotomized secondary veins arise from the midvein, except in lobes that show no midvein (Fig. 3a–c). Veins end into the margin and into the teeth when they are developed (Fig. 3a, b, d and e). Similar sterile (e.g., *Cladophlebis*, *Osmundophyllum*) and fertile (e.g., *Raphaelia*) foliage remains have described from the Cretaceous of Europe. Although these specimens closely resemble some species described from the Cenomanian of Czech Republic, such as *Raphaelia woldříchi* (Mařík,

1901; Velenovský and Viníklář, 1927), they are herein attributed to *Cladophlebis* because of the lack of fertile parts. Although many *Cladophlebis* species were proved to belong to Osmundaceae (van Konijnenburg-van Cittert, 2002), the present sterile material is only temporally assigned to this fern family until further evidence. A second fern type consists of several specimens. They usually show only sterile isolated pinnules, but one specimen bears two clusters of sporangia at the base of an entire oblong pinnule lamina (Fig. 3h). The base is lengthily tapered toward the rachis or petiole, and the apex is obtuse. Three to four time-dichotomized secondary veins arise from the midvein and end at the margin. These specimens much resemble

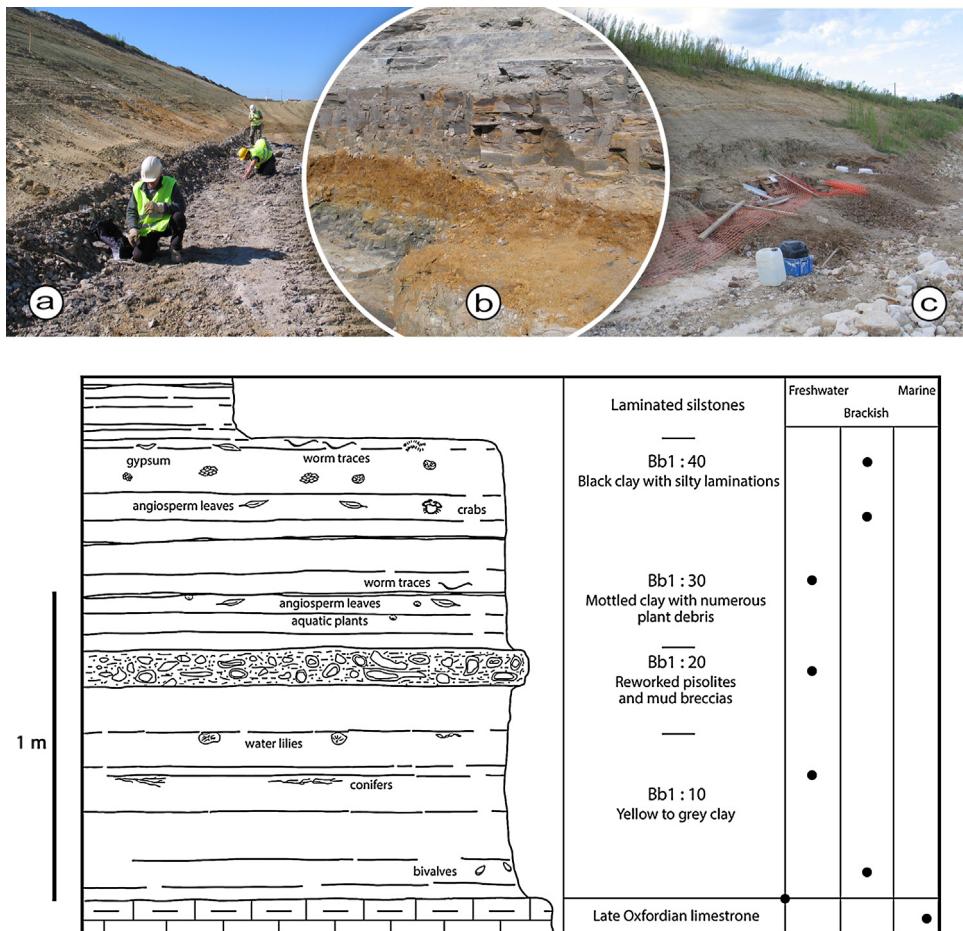

Fig. 2. Views of the excavations close to Jaunay-Clan. a-b: Ormeau-Saint-Denis locality (JCO), with detailed log and interpreted palaeoenvironments on subfigure 2; c: Bergère locality (JCB).

Fig. 2. Vues des différents chantiers de fouille près de Jaunay-Clan. a-b : localité d'Ormeau-Saint-Denis (JCO), avec log détaillé et les paléoenvironnements interprétés sur la sous-figure 2 ; c : localité de Bergère (JCB).

Osmunda regalis in shape and venation pattern of pinnules. *Osmundophyllum cretaceum* from the Bohemian Cenomanian is also quite similar (Frič and Bayer, 1901; Velenovský, 1889), but both the latter and the living royal fern usually show non-tapered pinnules with cordate bases, except for some apical pinnules. *Cladophlebis* and *Raphaelia*, or the Triassic-Jurassic *Todites* and *Osmundopsis*, show pinnules with a large insertion onto the rachis (e.g., Harris, 1961; van Konijnenburg-van Cittert, 1996). Our specimens are temporally ascribed to the genus *Osmundophyllum*. A third fern type consists of a single specimen showing a bi-pinnate fragment of frond (Fig. 3f). The rachises are very narrow, and bear elongate lanceolate pinnules. Pinnules are attached by a narrow base. The margin is entire. Venation is not observed. It resembles some schizaeaceous *Anemia*-like ferns, especially the Lower Cretaceous *Ruffordia goeppertiae* (e.g., Sender et al., 2005). It is noteworthy that in situ *Anemia*-like spores have been described in *Anemia* cf. *fremontii* from the Cenomanian of Horoušany, Czech Republic (Pálová and Kvaček, 2006). Pálová and Kvaček (2006) compared the associated sterile fronds with *Onychiopsis capsulifera* (Frič and Bayer, 1901; Velenovský, 1888), which

questions the latter generic attribution, since the genus *Onychiopsis* belongs otherwise to the Dicksoniaceae (e.g., Friis and Pedersen, 1990). A fourth fern type also consists of a single specimen with two or three broadly lobed pinnules (Fig. 3g). The pinnules are attached by a narrow base on the rachis. The venation consists of several time-dichotomized veins. It is attributed to the genus *Sphenopteris* based on the narrow base of insertion, the lobed lamina and the several time-dichotomized veins without a midvein. It is of uncertain systematic affinity.

Conifers are also poorly abundant and diverse. A first type consists of slender shoots showing two or three-branched stems and scale-like leaves (Fig. 4a and c). The leaves are tiny with a short free part, packed against the stem, and spirally arranged. They are ascribed to the genus *Brachyphyllum*, which representatives belong to several fossil and living conifer families. A second type consists of rare unbranched stems bearing spirally arranged leaves (Fig. 4b) and more abundant isolated leaves (Fig. 4d). In both, the laminar shape is obovate to oblanceolate. The base is lengthily tapered, and the apex is usually obtuse. The veins are equal. They arise parallel from the base.

Fig. 3. Ferns. a–e: *Cladophlebis* sp.; a–b: University of Poitiers–Ormeau-Saint-Denis (UP-JCO) 13-30a and b, pinna with lanceolate triangular pinnae, attached by a broad base on the rachis, with once to thrice dichotomous veins arising from the midvein; c: UP-JCO 13-35, distal part of pinna with oval to rounded pinnae, attached by a broad base on the rachis, with once to thrice dichotomous veins; d–e: UP-JCO 13-52a and b, pinna with lanceolate pinnules, attached by a broad base on the rachis, with once to thrice dichotomous veins arising from the midvein; f: UP-JCO 13-27, *Ruffordia goeppertiae*, frond with several elongate lanceolate pinnules; g: UP-JCO 13-31, *Sphenopteris* sp., pinna with broadly lobed pinnules, attached by a narrow base on the rachis, with several times dichotomous veins; h: *Osmundophyllum* sp., UP-JCO 13-59a, complete frond with three to four times dichotomous veins arising from the midvein and at the base of the lamina two clusters of spores. All scale bars are 10 mm.

Fig. 3. Fougères. a–e : *Cladophlebis* sp., a–b : UP-JCO 13-30a et b, penne avec pinnules lancéolées triangulaires, insérées par une base large sur le rachis, avec une nervation médiane et des nervures dichotomes ramifiées d'une à trois fois ; c : UP-JCO 13-35, partie terminale d'une penne avec pinnules ovales à rondes, insérées par une base large sur le rachis, avec des nervures dichotomes ramifiées d'une à trois fois ; d–e : UP-JCO 13-52a et b, penne avec pinnules lancéolées, insérées par une base large sur le rachis, avec une nervation médiane et des nervures dichotomes ramifiées d'une à trois fois ; f : UP-JCO 13-27, *Ruffordia goeppertiae*, fronde avec plusieurs pinnules allongées lancéolées ; g : UP-JCO 13-31, *Sphenopteris* sp., penne avec pinnules largement lobées, insérées par une base étroite sur le rachis, avec une nervation plusieurs fois dichotomes ; h, UP-JCO 13-59a, *Osmundophyllum* sp., fronde entière avec une nervation médiane d'où partent des nervures 3 à 4 fois dichotomes et, à la base du limbe, deux « grappes » de spores. Toutes les barres d'échelle font 10 mm.

Fig. 4. Conifers. a: *Brachyphyllum* sp., University of Poitiers–Ormeau-Saint-Denis (UP-JCO) 13-23, shoot several times branched with spirally arranged scale-like leaves; b: *Dammarophyllum* sp., UP-JCO 13-09a, shoot with spirally arranged oblanceolate leaves and parallel veins; c: *Brachyphyllum* sp., detail of 1; d: *Dammarophyllum* sp., UP-JCO 13-47a, isolated oval obovate leaf showing a long tapered base, parallel veins and an obtuse apex; e: *Pagiophyllum* sp., UP-JCO 13-08, stem bearing spirally arranged awl-shaped leaves with a long free part. Scale bars: 10 mm.

Fig. 4. Conifères. a : *Brachyphyllum* sp., UP-JCO 13-23, rameau ramifié plusieurs fois, avec feuilles écailleuses spiralées ; b : *Dammarophyllum* sp., UP-JCO 13-09a, rameau avec feuilles lancéolées spiralées et nervures parallèles ; c : *Brachyphyllum* sp., détail de 1 ; d : *Dammarophyllum* sp., UP-JCO 13-47a, feuille isolée ovale lancéolée montrant une base longuement atténueée, des nervures parallèles et un apex obtus ; e : *Pagiophyllum* sp., UP-JCO 13-08, tige portant des feuilles spiralées à longue partie libre. Barres d'échelle : 10 mm.

They converge near the apex when the lamina narrowed and end at or very near the margin. In the mid Cretaceous broad leaved conifers are included in several genera: *Dammarophyllum*, *Dammarites*, *Lindleycladus*, *Nageiopsis*, *Nageiopteris*, and *Podozamites*. *Dammarites* differ in

showing longer and wider linear, sessile leaves that arise from short tuberous stems, and end by acute apices ([Hluštík, 1976](#); [Kvaček, 2003](#)). *Nageiopsis* differs in having usually decurrent leaf bases and parallel veins that run straight into the apex margin without converging ([Kvaček,](#)

2003). *Lindleycladus* differs in having lanceolate leaves, strongly contracted but scarcely petiolate bases, distal ends tapering to blunt points, and outer veins ending by meeting margins at a small angle (Harris, 1979). *Nageiopteris* differs in having often axes with areas of close spirally arranged scars reminiscent of winter bud scales in extant conifers, and the veins do not converge and unite at the leaf apex Fontaine (1889, cited in Cantrill, 1991; Seward, 1919). *Podozamites* differs in showing contracted leaf bases, and veins spread proximally but were parallel for most of the leaf length (Cantrill, 1991; Seward, 1919). Thus, both leaved axes and isolated leaves are ascribed to the so far monospecific genus *Dammarophyllum* based on the leaf shape and venation pattern (Kvaček, 2003). A third type consists of a single, ill-preserved specimen (Fig. 4e). It shows an unbranched stem bearing spirally arranged, small awl-shaped leaves. The leaves show a long free part, a convex abaxial surface much larger than a concave adaxial surface, and a very acute apex. It is temporarily ascribed to the genus *Pagiophyllum* (Harris, 1979).

Angiosperms are by far the most abundant and diversified. All specimens are isolated leaves. Among them, several simple and petiole leaves show narrow, elongate, and lanceolate to linear laminas (Figs. 5a and b). The margin is entire. The primary venation is pinnate, and the secondary venation is brochidodromous, merging into bilateral intramarginal veins. Intersecondary veins branch exmedially. They correspond to *Eucalyptolaurus depreii*, also described from the Albian-Cenomanian of Charente-Maritime (Coiffard et al., 2009). Elliptic to obovate nanophylls show eccentric peltate attachment from which arise one medial primary vein and lateral veins that dichotomize several times before merging into an intramarginal vein (Fig. 5e). The margin is slightly undulated, and bears small glands. They correspond to *Ploufolia* erected based on specimens from the Albian of Spain and Portugal (Sender et al., 2010). Lastly, many leaf forms consist of a single specimen (Figs. 5c, d, f and g). Interestingly, angiosperm leaves show frequent and diverse insect bites.

4.2. Molluscs

Molluscs are rare, and the three forms distinguished below are represented by a single or a few specimens from the JCO locality. Costulated mytiloid specimens belong to the genus *Brachidontes* (Fig. 6c). Similar specimens are found in clayey plant beds from the Cenomanian of Arizona, USA (Kirkland, 1996) and Anjou, France (Néraudeau et al., 2013). Kirkland (1996) and Néraudeau et al. (2013) suggested that *Brachidontes*-bearing facies correspond to brackish coastal environments. A smooth, very asymmetrical and posteriorly very elongated shell is not identified, but it belongs more likely to marine coastal families, such as Mactridae, Pandoridae, and Tellinidae than to freshwater family such as Unionidae (Néraudeau et al., 2013). Thus, the shell shows a very oblique posterior truncation and a ventral margin shorter than the dorsal margin, an outline unknown for unionids and uncommon, but present, in some marine coastal bivalves. These features of shell morphology mostly resemble the living Pandoridae. However, "typical" *Pandora* species first appeared during the Eocene

and the Cenomanian representatives may have belonged rather to Mactridae or Tellinidae, which are known from the Cretaceous, though many species show posteriorly elongated shell without the same shell posterior truncation. A third and last form of subcircular shell appears closely related to the marine genus *Protocardia*. The three bivalve species of Jaunay-Clan are also associated in the Lower Cenomanian of Anjou, France (Néraudeau et al., 2013).

4.3. Arthropods

4.3.1. Crustaceans

Decapod crustaceans are represented in JCO section by one well-preserved specimen of brachyuran crab (Brachyura, Podotremata) with the carapace still being attached to the pereiopods (Fig. 6a and b). The carapace is relatively short, and the frontal margin shows wide orbits. The ventral side (Fig. 6b) shows the anterior thoracic sternites 1–4, suggesting that it corresponds to a male crab. The first left pereiopod bears a slender and robust chela. Despite these characters, the crab affinities are difficult to ascertain. It is close to the Dakoticancroidea that includes two fossil families: Dakoticancridae and Ibericancriidae. Interestingly, Dakoticancridae are restricted to the Late Cretaceous of North America and Northeast Mexico (Bishop, 1988; Rathbun, 1917, 1923; Vega and Feldmann, 1991), and Ibericancriidae are known from the Late Cretaceous of Spain (Artal et al., 2008) and of North America (Feldmann et al., 2013). Dakoticancroid crabs are only known from marine environments.

4.3.2. Insects

The single specimen from JCO (Fig. 7) consists of part and counterpart. It resembles the recent representatives of the subfamily Chrysomelinae (Chrysomelidae) in the following features: the outlines of all sclerites including elytra; the narrowly to moderately separated metacoxae; the diffuse and sparse coarse punctuation on the elytra; the procoxae moderately separated and somewhat transverse; the large pronotum slightly narrowing anteriorly but not or scarcely posteriorly; the comparatively long and stout femora and longer ventrite 1. Although the above list of similarities between the specimen examined and other members of chrysomelids is not enough to ground a more precise identification, the subfamily assignation is actually reliable. In addition, two isolated dragonfly wings have been recently found and are currently under study.

4.4. Vertebrates

A single, relatively poorly preserved, isolated feather has been found (Fig. 6d). Its preserved length is 21.5 mm. The calamus cannot be observed. The rachis is visible in the proximal part and becomes very thin and narrow distally. The feather displays pennaceous barbs organized in symmetrical closed vanes. The angle between the rachis and barbs is around 30 degrees. The barb density on each side of the rachis is 2 per mm. Barbules cannot be observed. This specimen can be interpreted as a body feather of an avian or non-avian theropod. Interestingly, a similar feather has

Fig. 5. Angiospermes. a–b: *Eucalyptolaurus* sp., University of Poitiers–Ormeau-Saint-Denis (UP-JCO) 13-54 and UP-JCO 13-55, two lanceolate to linear leaves showing a long tapered base, entire margin with intramarginal vein; c: UP-JCO 13-70, Ovate, petiolate leaf, slightly asymmetrical, with decurrent base, obtuse apex, and pinnate venation; d: UP-JCO 13-71, Elliptic to obovate leaf, strongly asymmetrical, with retuse apex; e: *Ploufolia* sp., UP-JCO 13-90, obovate nanophyll with eccentric peltate attachment, one medial primary vein and lateral veins that dichotomize several times; f: UP-JCO 13-72, Elliptic, petiolate leaf, with asymmetrically decurrent base, retuse apex, and pinnate venation; g: UP-JCO 13-75, oblong, petiolate leaf, asymmetrically decurrent base, obtuse apex, and pinnate venation. Scale bars: 10 mm.

Barres d'échelles : 5 mm (4-6) et 10 mm (1-3).

been recently described from the contemporaneous beds of another plant-bearing Lagerstätte of western France (Vullo et al., 2013).

4.5. Ichnology

Two types of trace fossils have been found in the plant-bearing clayey beds of Jaunay-Clay. The first,

relatively common, trace type corresponds to meandering, smooth, non-branching burrows generally less than 30 mm in length. Their maximum width is about 4 mm, and both extremities become progressively thinner. They can be assigned to *Cochlichnus anguineus*, a widespread ichnospecies known for instance from the Wealden strata of England (Goldring et al., 2005). Several *Cochlichnus* traces are often present on the same plate, sometimes

converging on a larger, poorly defined trace fossil (ichno-genus cf. *Lockeia*) (Fig. 6e).

The second trace fossil is represented by a single indeterminate trackway (less than 10 mm in width), probably made by a small invertebrate. It shows a median, longitudinal groove flanked on both sides by a series of short (less than 3 mm), regularly arranged, perpendicular marks (Fig. 6f).

5. Discussion

Plant assemblages of Jaunay-Clan consist of a mixture of few ferns and conifers with very abundant and diverse angiosperms. The family Osmundaceae is represented by the genera *Cladophlebis* and *Osmundophyllum*, while the family Schizaeaceae includes *R. goeppertii*. The conifers are of uncertain systematic affinities including the genus *Dammarophyllum* that belongs to either Araucariaceae or Podocarpaceae based on the Florin ring present around the stomatal pit. Angiosperms include probable Nymphaeales (*Ploufolia*), Magnoliids (*E. depreii*) and diverse Eudicots.

The fossil plant assemblage mostly consists of isolated leaves with the petioles showing basal, slightly widened, insertion scars. There are a few leafy stems of conifers (*Brachyphyllum*, *Pagiophyllum* and *Dammarophyllum*) that

still have leaves in connection to the stems. However, the leaves and leafy stems were probably produced by natural loss after normal senescence. Insect leaf bites are frequent especially in angiosperm leaves. However, wounds usually show thickened rims around that indicate that plant parts healed and survived for a while. Insect leaf bites are diverse, suggesting they were produced by various insect types (Chapuis, 1874). Based on the diversity, the completeness and the absence of abrasion, the transport was probably short and/or calm. Parautochthony is probable for the fossil plants, but the occurrence of numerous Nymphaeales *Ploufolia* remains suggests a freshwater episode in a pond-like environment. The presence of brackish to marine mollusks and a specimen of Dakoticancroid crab below and above the Nymphaeales beds respectively indicate that the freshwater episode has interrupted a brackish sedimentation trend in a paralic, coastal basin (see interpretation on Fig. 2b).

The single leaf beetle collected displays the typical characters of the family Chrysomelidae usually considered as advanced. Data published about fossils of this family are quite ambiguous. Although some chrysomelids were reported from the Triassic and Jurassic (Heer, 1877; Santiago-Blay, 1994), most of them do not quite resemble cucujiformians (infraorder Cucujiformia). During a long time, the subfamily Protoscelinae from the Upper

Jurassic of Karatau (Karabastau Formation, Kazakhstan) was regarded as the earliest chrysomelids. However, Legalov (2013) showed that this subfamily must be included in the superfamily Curculionoidea (Anthribidae Billberg, 1820). Besides, *Tarsomegamerus* was initially described as a leaf beetle from the Middle Jurassic of Daohugou (Jiulongshan Formation Inner Mongolia, China: Zhang, 2005), but it was later transferred to the infraorder Elaterifor (Kirejtshuk et al., 2010a; Kirejtshuk and Azar, 2013b; Eulichadidae Crowson, 1973). Nevertheless, the family Chrysomelidae could appear as one of the earliest cucujiformian groups (Kirejtshuk, 1994). Wolf-Schwenninger and Schwaller (2007) ascribed to the subfamily Eumolpinae leaf beetle from the Lower Cretaceous of Santana (Crato Formation, Brazil). Kirejtshuk et al. (2010b) reported one chrysomeloid group probably related to Aulacoscelinae and beetles like Hispinae from the Lower Cretaceous of Chaomidian (Yixian Formation, Liaoning Province, China). More detailed review of the fossil record is given by Kirejtshuk and Ponomarenko (2013a). Thus, it is likely the finding of a member of subfamily Chrysomeliniae *sensu stricto*. Based on trophic interactions of living members of this subfamily, this fossil species could have feed on angiosperms rather than on gymnosperms.

More new localities were collected during field prospections in marine Cenomanian sediments close to the villages of Saint-Léger la Pallu (close to Marigny-Brizay) and Scorbé-Clairvaux. They contain diverse fossil vertebrate remains including selachians, bony fishes and reptiles (chelonians, crocodyliforms, elasmosaurid plesiosaurs, ornithocheirid pterosaurs, the snake *Simoliophis*) and sometimes a few small amber drops. They are currently under more detailed study.

The new localities from the Lower Cenomanian of Jaunay-Clan offer new perspectives on the diversity and evolution of ecosystems in Europe, especially concerning angiosperms and arthropods during the Cretaceous.

Disclosure of interest

The authors declare that they have no conflicts of interest concerning this article.

Acknowledgements

This work was conducted under an agreement for paleontological researches signed between LISEA and COSEA (VINCI group) and the PALAIOS society represented by X. Valentin and approved by B. Godinot and H. Tricot in June 2012. We thank C. Macary, M. Leroy and B. Massol for authorizations and C. Sandre, P. Stigliani and J. Vincent of the administrative team for support management. We also thank P. Chadeyron, M. Lafaurie and V. Marquis for support assistance and P. Bégou, E. Hébrant and P. Brocheriou for excavation management. Financial supports were also provided by the CG of Vienne, le Pays Chauvinois and the area of Valdiveinne. We especially thank the local officials: Senator A. Fouché, the mayors R. Laurendeau and M. Bigeau and the comity of R. Benoit and P. Bastier. We warmly thank F. Auvray, M. Barkat, P. Bastier, R. and J. Benoit, G. Bertrand, D. Berthé, E. Blandin, R. Bouet, T. Capillon, H. Châtelier,

T. Coillot, G. Cretin, S. and E. Dépré, J. Drochon, D. Duchène, P. Frey, A. Gris, C. Gros, B. Guevel, L. Haise, J.-F. Hilairet, A. Kociuba, P. Lacroix, V. Lazzari, F. Lapalus, A. Lemaitre, N. Mathé, P. Paquereau, S. Pecot, M. and J.-C. Petelaud, M. Pouyillon, F. Robin, J.-M. Terrasson, C. and V. Texier, G. Thiery, D. Tornais, S. Tortora, N. Trassard, O. Vérité and A. Vilaneau for prospections and works in the fields. We thank G. Breton, M. Daccordi (Museo Civico di Storia Naturale, Verona), P. Godefroit (IRSNB), A. Nel (MNHN) and A.G. Moseyko (Zoological Institute of the Russian Academy of Sciences) for scientific discussions. P.A. Kirejtshuk drew the beetle specimen. We are most grateful to A. Brunelliére (UP) and S. Riffaut (UP) for technical support.
